Introduction

Motivation

- NCEP Global Forecast System (GFS) model loses atmospheric water vapor over tropical west Pacific during 7-day forecast

Mean Precipitable Water (PW) Error (mm) 8 July–7 November 2014

24-h GFS Forecast

168-h GFS Forecast

forecast minus analysis

western North Pacific region

60N 30N 0 120E 150E 180 150W 120W 90W 60W 30W 0

6 4 2 0 -2 -4 -6 mm

60N 30N 0 120E 150E 180 150W 120W 90W 60W 30W 0

- PW loss in GFS forecasts is prevalent during quiet regimes (no tropical cyclone present)

- GFS produces too much rain in 0–24 h forecast and gradually decreases thereafter

- GFS Simplified Arakawa-Schubert (SAS) cumulus scheme drives burst of convection early in the forecast, contributing to stabilization, drying, and suppression at longer forecast leads

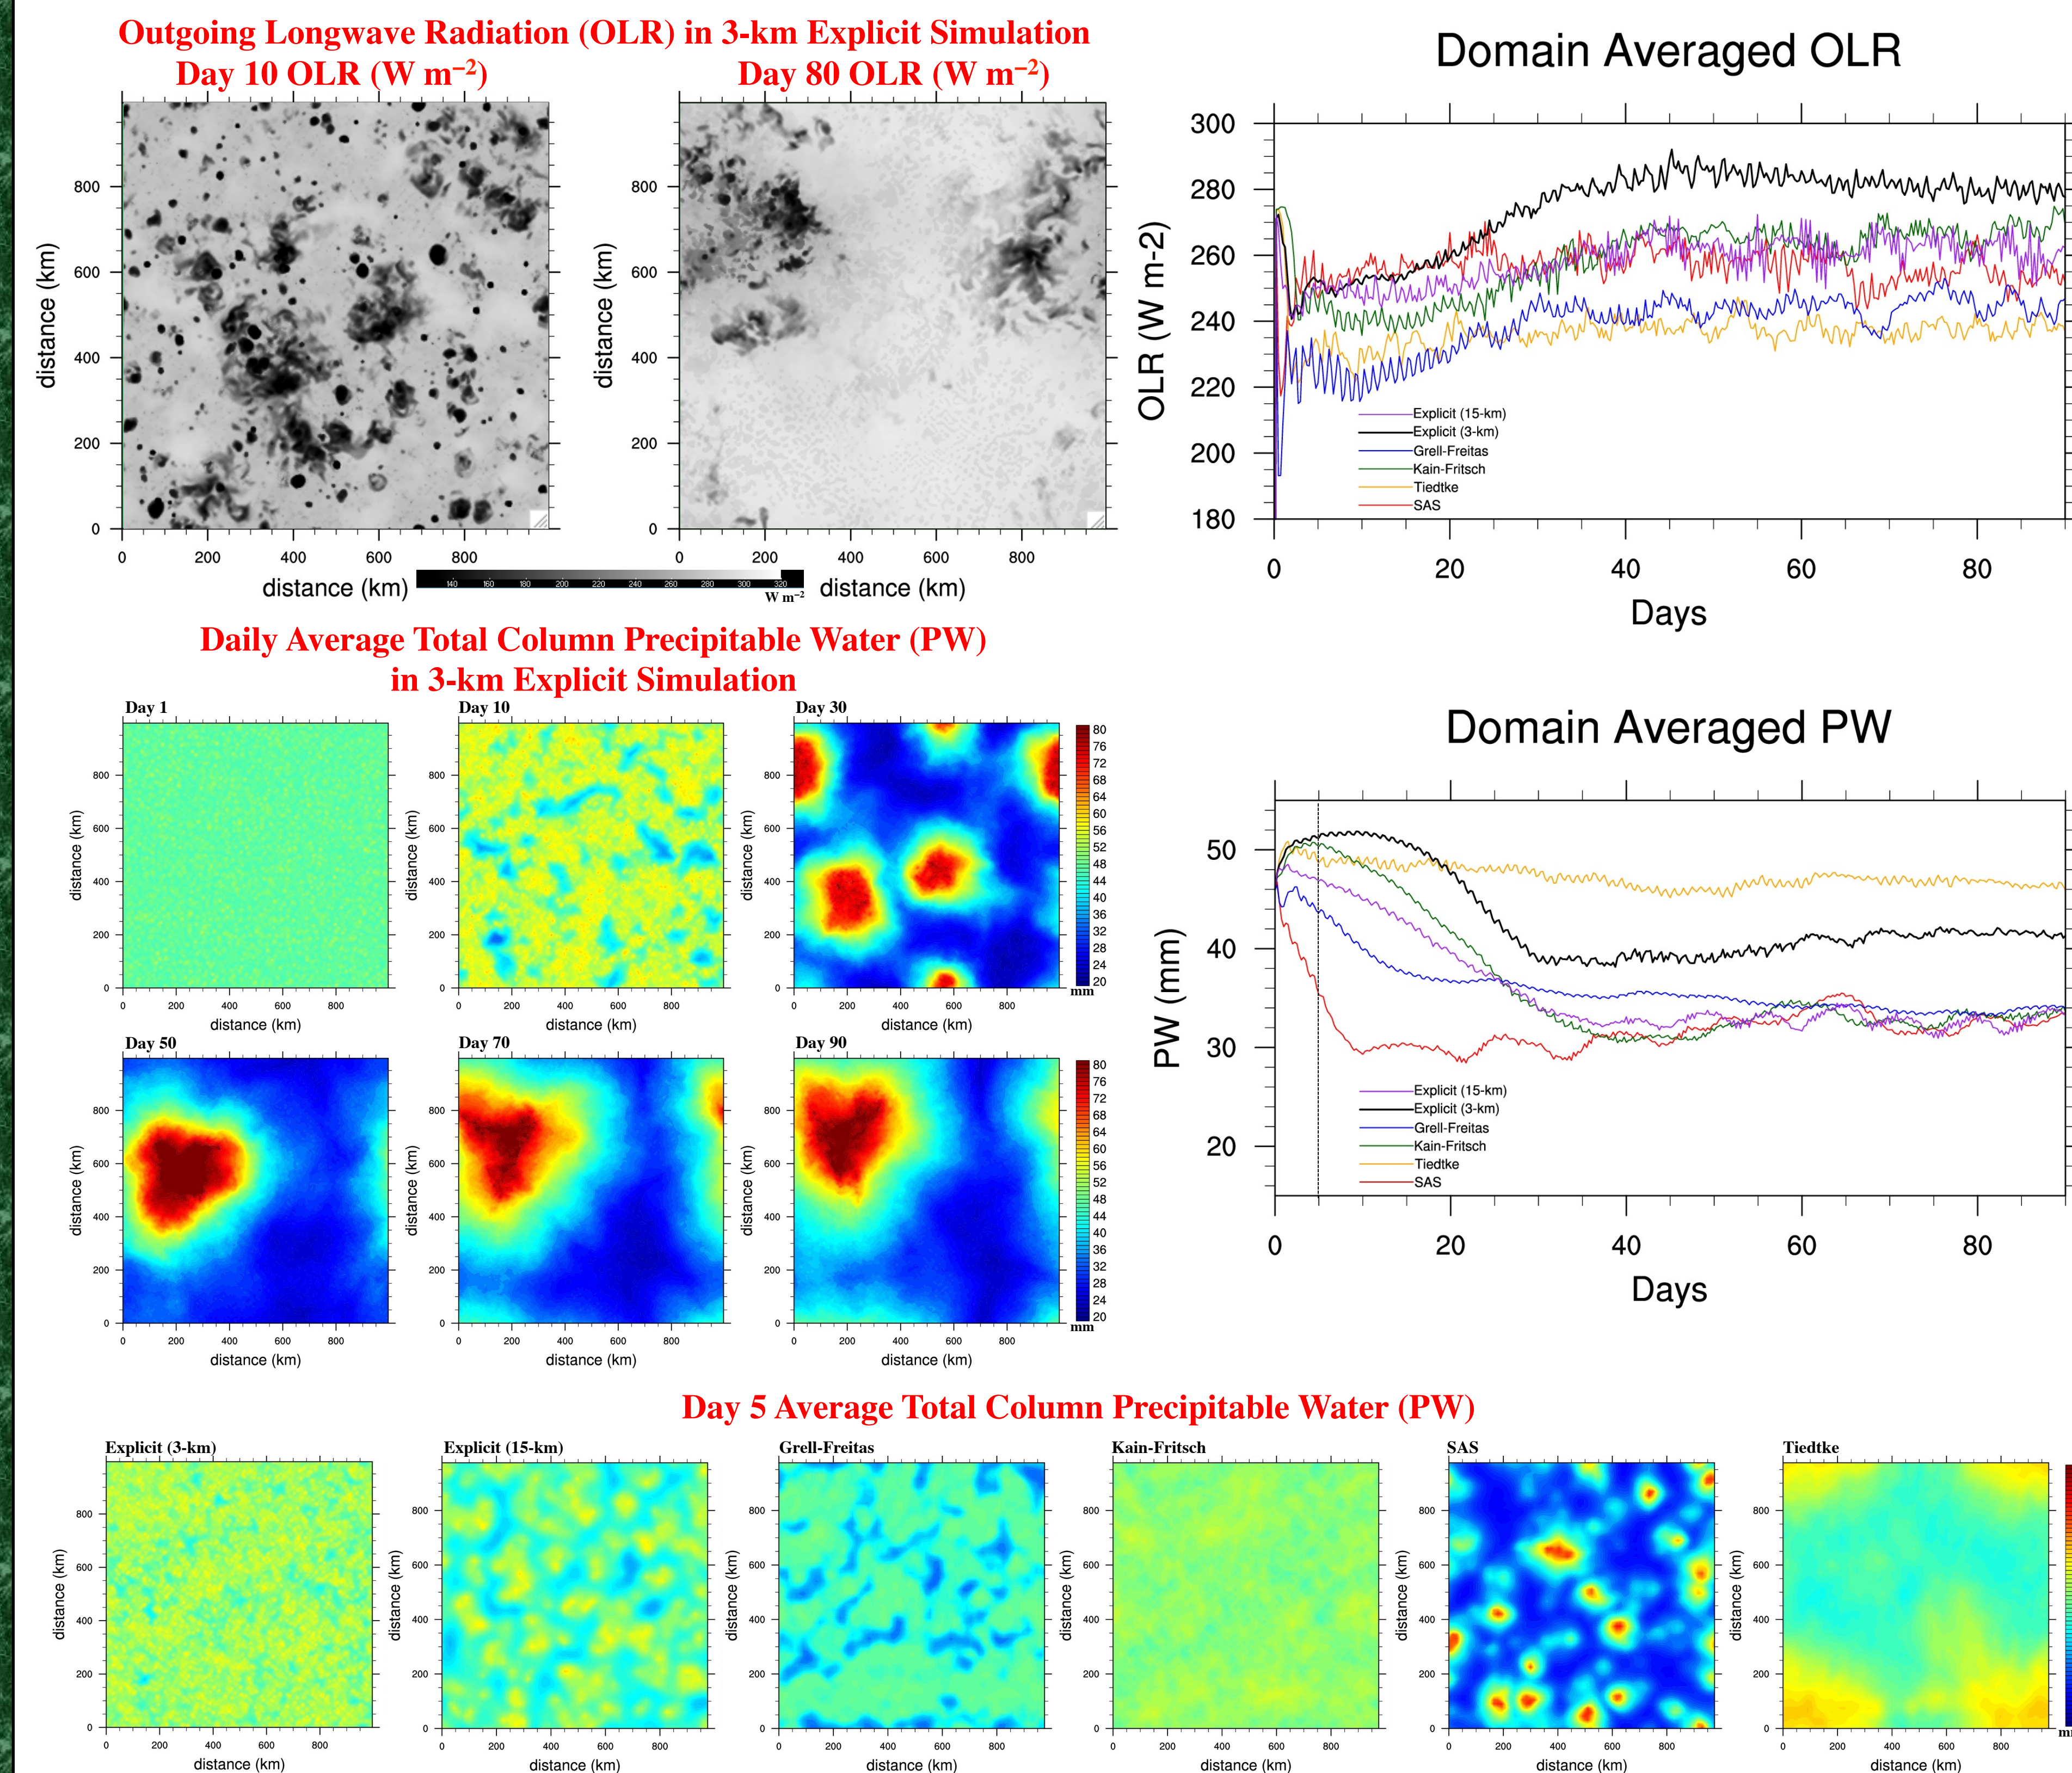

- We aim to use WRF idealized framework to isolate behavior of SAS cumulus parameterization

WRF-ARW Idealized Experiments

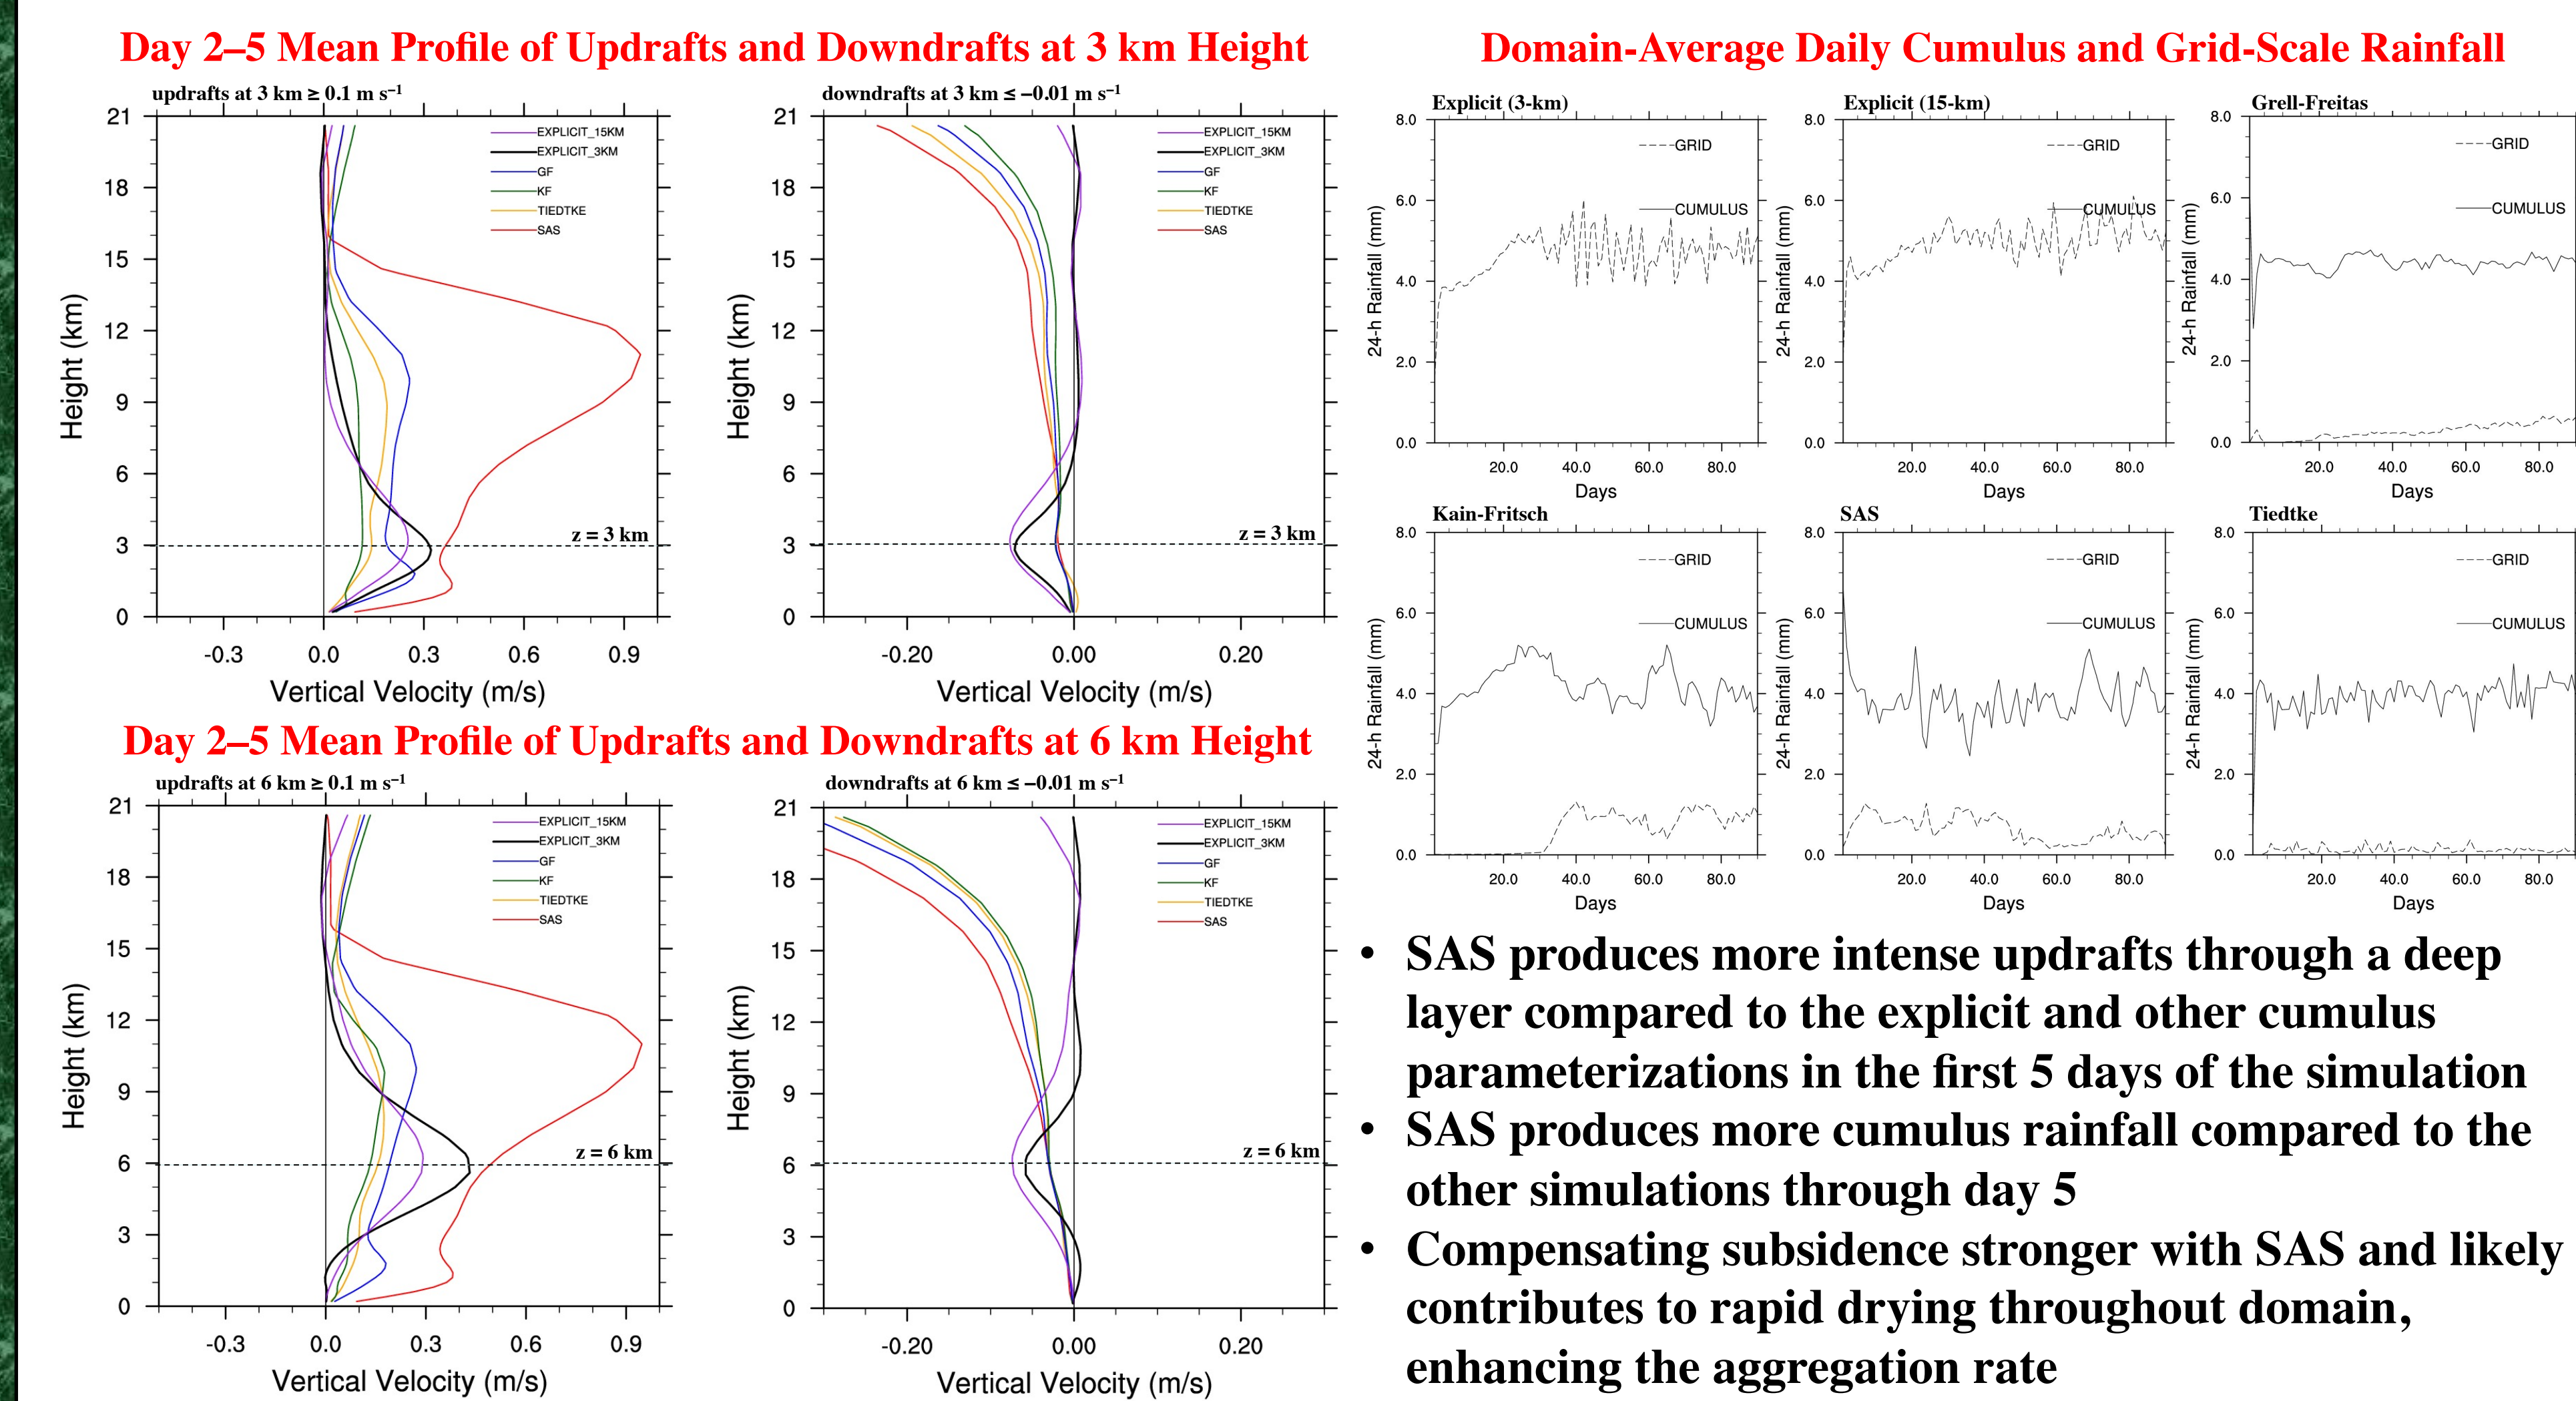

- 90-day WRF-ARW (v3.6.1) simulations
- 15-km horizontal (67×67) grid spacing
- 44 vertical levels to 30 km
- No coriolis; no wind; periodic lateral BCs
- Fixed sea surface temperature = 303 K
- Initial sounding from radiative-convective equilibrium solution of Rotunno and Emanuel (1987)
- Initiate convection with ± 0.5 K thermal perturbations in lowest 10 model levels
- Morrison microphysics, RRTMG radiation, YSU PBL, 6th order diffusion
- Test SAS, Tiedtke, Kain-Fritsch, and Grell-Freitas cumulus schemes at 15-km
- Compare results with explicit runs at 15 km and 3 km horizontal (334×334) grid spacing

Results

Aggregation in Idealized Simulations

- The 3-km explicit WRF simulation reaches radiative-convective equilibrium (RCE; aggregated convection) by day 40, similar to previous studies
- The 15-km explicit and Kain-Fritsch simulations behave similar to the 3-km simulation, while Tiedtke and Grell-Freitas reach RCE by about day 30
- The SAS is an outlier, reaching RCE by day 20 and characterized by rapid domain-average drying during the first 10 days of the simulation

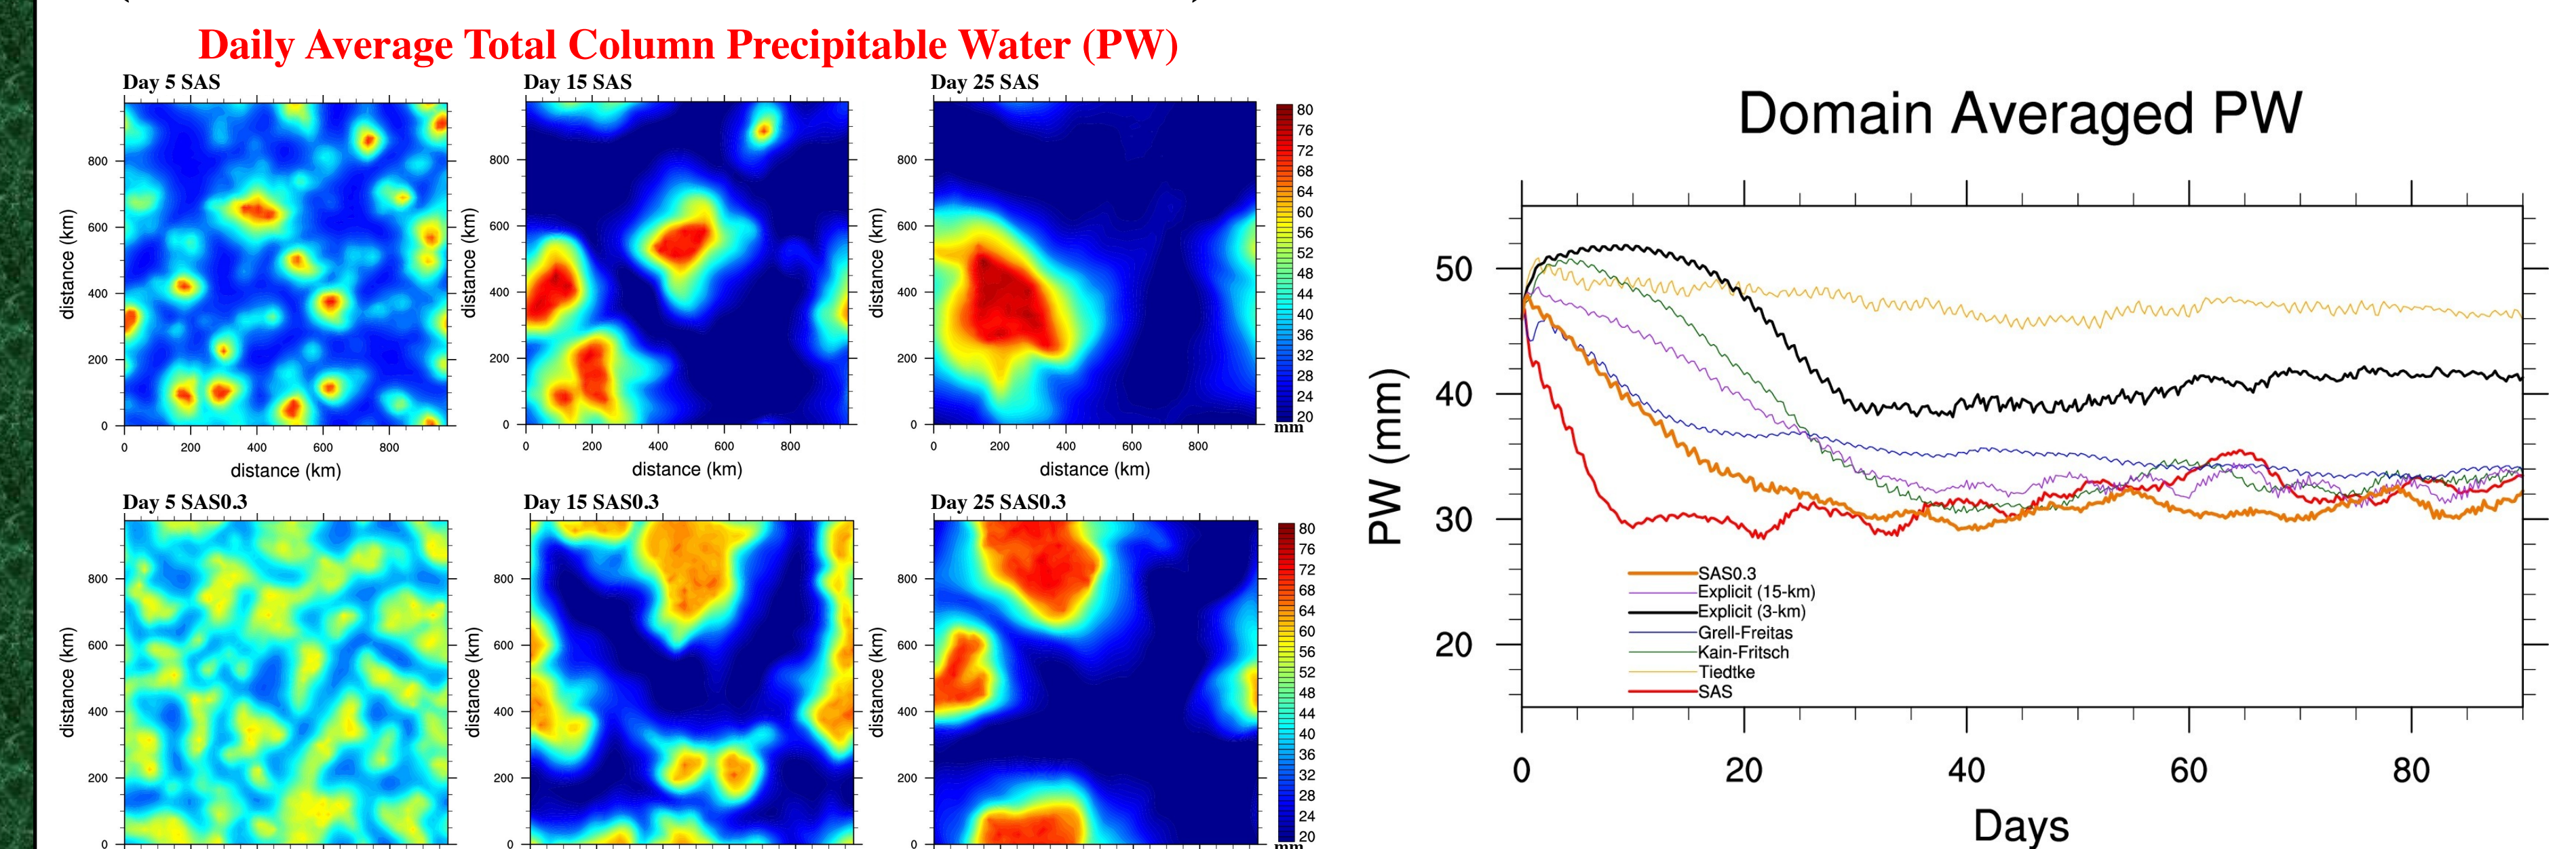

- SAS produces more intense updrafts through a deep layer compared to the explicit and other cumulus parameterizations in the first 5 days of the simulation
- SAS produces more cumulus rainfall compared to the other simulations through day 5
- Compensating subsidence stronger with SAS and likely contributes to rapid drying throughout domain, enhancing the aggregation rate

Results

Test Modification to SAS Entrainment Parameter

- Bassill (2015) noted sensitivity of track forecasts of Hurricane Sandy to the deep convective entrainment parameter in SAS
- Increasing the entrainment parameter reduces deep convection driven by SAS, which produces less drying and allows for more grid-scale saturation
- As a preliminary test, we increase the SAS entrainment parameter to 0.3 (simulation referred to as “SAS0.3”) from the default value of 0.1

Conclusions

- Compared to WRF simulations that utilize explicit convection or other cumulus parameterizations, SAS produces more intense convection early in the simulation that enhances the domain-average drying and aggregation of convection
- Increasing the deep convective entrainment parameter in SAS “dampens” the rate of drying/aggregation in the first 10 days, but does not change the model “climatic state” after day 30 compared to other cumulus schemes
- Behavior of SAS in WRF simulations is somewhat consistent with operational GFS forecasts over the west Pacific, but with caveat that SAS may behave differently in simulations using the WRF versus GFS modeling systems
